Electronic and transport properties of a short Ni nanowire suspended between two semi-infinite ferromagnetic Ni leads are explored in the framework of density-functional theory. The spin-dependent ballistic conductance of the nanowire is calculated using a scattering-based approach and the Landauer-Büttiker formula. The total calculated conductance in units of $G_0 = 2e^2/h$ is around 1.6, in fairly good agreement with the broad peak observed around ~ 1.5 for the last conductance step in break junctions. Separating contributions from different spins, we find nearly $0.5 G_0$ from the majority spin s -like channel, whereas the remaining minority spin conductance of $1.1 G_0$ contains significant contributions from several d states, but much less than $0.5 G_0$ from s states. The influence of the structural relaxation on the magnetic properties and the ballistic conductance of the nanowire is also studied.

INTRODUCTION

Modern experimental techniques involving ballistic conductance measurements in tip-based devices or in mechanically controllable break junctions allow the study of contacts of ultimate dimensions consisting of just a single atom, or of a short monatomic wire in the constriction. Investigations of metal nanocontacts during elongation show that the conductance decreases stepwise following atomic rearrangements. In noble metals (Cu, Ag, Au) and alkali metals (Li, Na, K) the last conductance step before breaking, most likely corresponding to a monatomic contact or a nanowire, takes a value close to G_0 ($G_0 = 2e^2/h$ is the conductance quantum)[1] which corresponds to the free propagation of two s -like conduction electrons, one per spin. Transition metal nanocontacts (e.g., Ni, Co, Fe) whose atoms have a partially occupied d shell, also display conductance steps but show less clear evidence for conductance quantization. Some conductance histograms for Ni [2, 3] and Fe [4] nanocontacts exhibit a well-defined first peak near $1 G_0$; some others show a striking fractional peak at $0.5 G_0$ in Ni [3, 5] and Co.[5] Generally, however, low temperature break junction measurements on Ni, Co, and Fe nanocontacts find a broadly peaked conductance histogram well above $1 G_0$. Untiedt *et al.*[6] reported a value at roughly $2 G_0$ (in Fe) and $1.3 G_0$ (in Co and Ni) while Bakker *et al.*[7] found a conductance peak at $1.6 G_0$ in Ni.

A variety of methods have been developed to address theoretically the problem of electron transport in atomic scale conductors.[8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18]. Choi and Ihm[18] in particular proposed a complex wave-vector band method particularly suitable for implementation within standard plane-wave ab-initio density functional pseudopotential approaches. Owing to their ex-

ponential decay, complex wave-vector Bloch states provide the spatially localized states crucially involved in the lead-nanocontact-lead wave-function matching. For application to transition metal nanocontacts, we recently presented[19] an extension of Choi and Ihm's method to ultrasoft pseudo-potentials, making the treatment of very localized d states accessible with a plane-wave basis set. The method was applied to study the effect of a magnetization reversal on electron transport in infinite monatomic Co and Ni nanowires.[19] Interestingly, these calculations showed that a spin reversal can completely block all the d channels at the Fermi energy, causing a large "ballistic magneto-resistance" and leaving a conductance of only $\sim 1 G_0$ of the freely propagating s -like states of both spins. However, the nanocontact geometry could not be addressed by such a tipless calculation, which omits completely the finite electron reflection at the contact. In this paper we use the same method to fully include the tips, and explore the joint effects of the geometrical constriction and of magnetism on the ballistic transport of a magnetic metal like Ni.

For our purpose, we consider an idealized system consisting of a three-atom Ni monatomic nanowire placed between two semi-infinite Ni(001) bulk-like "leads". Actually, break junction experiments showed spontaneous formation of monatomic nanowires only for the heavy $5d$ metal nanocontacts (Ir, Pt, and Au).[20] whereas only transmission electron microscopy showed evidence of such short nanowire contacts of lighter transition metals such as Co and Pd.[5] Our calculation is intended as a case nanocontact study, rather meant to explore than to affirm one particular geometry and its effects. We note that recently Bagrets *et al.*[21] performed similar calculations for the three-atom Co nanowire while Jacob *et al.*[22] studied ballistic transport in a single-atom Ni contacts using a cluster embedded method;[9] we shall

FIG. 1: Supercell used for simulating a three-atom Ni wire suspended between two semi-infinite Ni(001) leads.

later compare our results with their calculations.

CALCULATIONS: GEOMETRY, RELAXATION, AND MAGNETISM

Electronic structure calculations are carried out within the spin density functional theory, using the standard plane-wave PWscf code.[23] The spin-polarized version of the generalized gradient approximation (σ -GGA) in the form introduced by Perdew, Burke, and Ernzerhof[24] is used for exchange-correlation functionals. Ni atoms are described by ultrasoft pseudo-potentials[25] with parameters given in Ref. 26. The cutoff kinetic energies were 25 Ry and 250 Ry for the wave functions and for the charge density, respectively. Integration over the Brillouin Zone (BZ) up to the Fermi energy was performed by using special k points[27] and a standard broadening technique[28] with a smearing parameter of 0.02 Ry. Periodic boundary conditions are assumed in all three directions. The supercell used to simulate a three-atom Ni nanowire contact is shown in Fig. 1. A $(2\sqrt{2} \times 2\sqrt{2})$ periodicity is employed in the xy plane which keeps the periodically repeated wires sufficiently apart from one another so that their mutual influence can be neglected. The bulk “tips” are simulated by the two opposite (001) faces of a planar slab consisting of seven atomic (001) crystalline planes (8 atoms per plane), quite sufficient to reproduce a bulk-like potential in the middle of the slab. Since the supercell is very large along [001] (the z axis), the BZ in this direction is sampled only at $k_z = 0$ while in the (k_x, k_y) plane perpendicular to the wire convergence demanded instead ten two-dimensional (2D) special k points. This sampling of the BZ was found to be sufficient for obtaining a converged self-consistent potential needed for subsequent transmission calculations.

We started with an ideal unrelaxed atomic configuration where the end atoms of the wire are positioned at the ideal hollow sites of Ni(001) surfaces, their dis-

TABLE I: Structure of the three-atom Ni wire suspended between two Ni(001) leads in unrelaxed and relaxed configurations: relaxation of the first interlayer spacing in the leads (Δ_{12}), lead-nanowire separation (D), and interatomic distance in the nanowire (d). Some relevant theoretical data for the Ni(001) surface and for the infinite Ni nanowire are also provided.

	Δ_{12} (%)	D (Å)	d (Å)
unrelaxed wire	0.0	1.76	2.49
relaxed wire	$-0.8 \div -2.8$	1.47	2.19
Ni(001) surface ^a	-3.6	—	—
infinite Ni wire	—	—	2.17

^a Ref. 30

tance D (see Fig. 1) to the surface planes being $a_0/2$ ($a_0 = 3.52$ Å is the lattice constant of the bulk Ni). The intra-wire spacing d was initially set equal to $a_0/\sqrt{2}$ which is the nearest neighbor distance in the fcc Ni. We then relaxed structurally this configuration, using a simplified (2×2) planar geometry (4 atoms per layer representing the bulk) and fifteen special k points in the 2D BZ, which reduced the computational weight. Minimizing total energy, all atomic positions were allowed to relax, including the distance parameters D , d , and the length L of the supercell along the z axis. During relaxation the wire was constrained to remain straight and no zig-zag-like configurations were considered. Some calculated quantities describing the geometry of the system are listed in Table 1. In particular, we found that the first interlayer distance in the leads is contracted with respect to the ideal unrelaxed value $d_{12}^0 = a_0/2$ by value of $0.8 - 2.8\%$.[29] These values are, however, less than the corresponding one (3.6% d_{12}^0) calculated for the unperturbed, contact free Ni(001) surface[30] reflecting the influence of the nanowire bridging two surfaces. As expected, the most significant geometry change occurs in the positions of the nanowire atoms. Here, both the end distance D and the central spacing d contract significantly during the relaxation. The value of d (2.19 Å) is in fact very close to the calculated zero-stress interatomic spacing in the infinite monatomic wire (2.17 Å). The atomic positions obtained after relaxation were subsequently used to construct our final system with a larger $(2\sqrt{2} \times 2\sqrt{2})$ planar periodicity,[31] that would have been much more expensive to optimize directly.

LSDA calculations were carried out for this geometry, comprising a total of 59 Ni atoms. In Figs. 2a and 2b we show the local magnetization after averaging in the xy plane as a function of z for unrelaxed and relaxed atomic configurations, respectively. The total magnetization in the lead region (marked by the dashed lines) was divided by 8 – the number of atoms per layer. The central layer magnetization is quite close to the theoretical[30] and experimental[32] value $0.61 \mu_B$ for magnetic moment of

FIG. 2: The xy integrated magnetization as a function of z for the tip suspended three-atom Ni wire in unrelaxed (a) and relaxed (b) configurations. Magnetic moments (in the Bohr magneton) at some atoms are also given.

bulk Ni. The local magnetization grows when moving from bulk-like internal layers to the surface layer and further to the central atom of the nanowire. This reflects a common tendency in d -band metals (e.g., Ni, Co, and Fe) for the magnetic moment to be enhanced in conditions of reduced coordination, as found in systems with reduced system dimensionality where the d bands are narrower. The magnetic moments of the atoms at the tip surface and of those in interior layers ($\mu_{S1} = 0.72 \mu_B$ and $\mu_{S2} = 0.64 \mu_B$) compare well with the corresponding values calculated for the Ni(001) surface[30] ($0.76 \mu_B$ and $0.68 \mu_B$). Very reasonably, magnetization in the lead region was found to be quite insensitive to the structural relaxation. On the contrary, magnetic moments on the nanowire atoms reduce significantly during the relaxation as a consequence of a significant shortening of interatomic bonds. In particular, the magnetic moment on the central nanowire atom drops from $1.22 \mu_B$ to $1.07 \mu_B$. These values are very close to those ($1.19 \mu_B$ and $1.13 \mu_B$) for an infinite monatomic wire calculated at the corresponding interatomic distances.

ELECTRON TRANSMISSION THROUGH THE NANOCONTACT

Conductance is the main measurable physical quantity in nanocontacts. Owing to their small size, usually well below the electron mean free path, resistive processes of diffusive and of inelastic origin are generally negligible in nanocontacts, where even at room temperature the conductance is ballistic. In the linear response regime (i.e., at very small applied voltages) the ballistic conductance of an open system consisting of the nanocontact connected to two semi-infinite leads is related to

the total transmission function at the Fermi energy by the Landauer-Büttiker formula: $G = (1/2)G_0T(E_F)$, where $G_0 = 2e^2/h$ is the conductance quantum. In our spin density functional picture electrons of different spin move independently in their different self-consistent potentials. The two spin channels are uncoupled and can be treated independently, so long as the spin-flip processes are neglected, and the total transmission is the sum of contributions from the two spin channels: $T(E) = T_\uparrow(E) + T_\downarrow(E)$. In our transmission calculation, we consider the system shown in Fig. 1 as the nanocontact scattering region, ideally attached to semi-infinite leads on both sides. To obtain electron transmission at energy E we first construct the generalized Bloch states (consisting of propagating and evanescent states) which are solutions of the Kohn-Sham equation at energy E of hypothetical infinite lattice-periodic leads. These states are then used to construct the scattering states of the entire lead-nanocontact-lead system and to calculate the transmission function. Full details are given in Ref.[19].

Our supercell geometry encompasses an infinite number of nanowire replicas forming a square supercell lattice in the xy plane. The transmission (per supercell) of such infinite set of nanocontacts is given by an integral over the 2D BZ of a transmission that depends on $\mathbf{k}_\perp = (k_x, k_y)$:

$$T(E) = \frac{S}{(2\pi)^2} \int T(E, \mathbf{k}_\perp) d^2\mathbf{k}_\perp, \quad (1)$$

where S is the area of the supercell in the xy plane. What we are interested in, however, is the transmission of a single isolated nanocontact; we should therefore try to attain the limit of an infinitely large supercell. One could approach this limit in many different ways, for example by calculating transmission at some $\mathbf{k}_\perp$ (e.g., at the $\bar{\Gamma}$ point, $\mathbf{k}_\perp = 0$) or else by integrating the transmission over the 2D BZ as in Eq. 1. For a sufficiently large supercell the 2D BZ will collapse to a point, so that the transmission function will not depend on $\mathbf{k}_\perp$ and the two approaches will eventually give the same limiting result. We found, however, that upon increasing the supercell xy size the correct single nanocontact limiting value for transmission function is approached much faster in the second case. In particular, for a manageable supercell size such as $(2\sqrt{2} \times 2\sqrt{2})$ the $\mathbf{k}_\perp$ point integration of the transmission function is crucial since it turns out to depend much on the $\mathbf{k}_\perp$, as illustrated in Fig. 3 where the minority spin channel transmission of a three-atom Ni nanowire (in relaxed configuration) is presented for the different $\mathbf{k}_\perp$ values shown in the insets. The transmission function varies significantly from one $\mathbf{k}_\perp$ to another reflecting a different coupling between the nanowire and the lead states. In particular transmission at the Fermi energy, which gives the conductance, changes quite noticeably with $\mathbf{k}_\perp$. The fully $\mathbf{k}_\perp$ -integrated transmission (obtained by using 10 special $\mathbf{k}_\perp$ points) is provided for

FIG. 3: Transmission versus energy for the minority spin channel of the (repeated) Ni nanowire in relaxed configuration, calculated at different $\mathbf{k}_\perp$. Selected $\mathbf{k}_\perp$ values are shown on insets. The numerical value of transmission at the Fermi energy – representative of ballistic conductance at zero voltage – is also given for each curve. The transmission function obtained by averaging over the full set of 10 special $\mathbf{k}_\perp$ points, closest to the single nanowire conductance, is plotted as the dashed curve on the lowest panel.

comparison in the lowest panel (dashed curve). Here $\mathbf{k}_\perp$ -averaging makes the transmission curve smoother, eliminating several fluctuations and retaining only smoother features attributable to the isolated nanowire. We verified in fact that this $\mathbf{k}_\perp$ -integrated conductance depends much less on the supercell size than any of the selected $\mathbf{k}_\perp$ points, and is thus the best approximation to that of the isolated nanowire. The importance of proper sampling of the 2D BZ for ballistic conductance calculation was also pointed out recently by Thygesen *et al.*[34] In conclusion we systematically integrated the transmission function over the 2D BZ of a $(2\sqrt{2} \times 2\sqrt{2})$ xy supercell by averaging over 10 special $\mathbf{k}_\perp$ points in the irreducible sector of the 2D BZ.[33]

CONNECTION WITH ELECTRONIC STRUCTURE

Before discussing the overall ballistic conductance results for the Ni nanowire we wish to discuss the electronic structure of the supercell used to calculate the self-consistent potential. As we shall show, at each $\mathbf{k}_\perp$ there is a clear correlation between sharp features in the transmission as a function of energy and the electronic

structure of the supercell. Let us consider in particular the dispersion of states with k_z . If the nanocontact were cut, all the states would be z -localized inside the lead block, forming a dense set of states that are flat in k_z , totally devoid of dispersion. When the nanocontact is established, a majority of these states remain still localized inside the lead, but a few extended states appear, characterized by k_z dispersion. These extended states are not necessarily easy to identify, because as a function of k_z they (anti-)cross the dense lead localized states. Yet, those extended states that cross E_F are responsible for the nanocontact ballistic conductance.

For illustration, we choose the $\bar{M}$ point of the 2D BZ. In Figs. 4 and 5 we present electron bands of the three-atom Ni nanowire (relaxed configuration) in the z direction for majority and minority spins, respectively. We classify the electron states in terms of the orbital angular momentum m around the nanowire axis. Though in our geometry the m is not strictly a good quantum number due to the presence of the leads, all the electron states at the $\bar{M}$ point (as well as at the $\bar{\Gamma}$ point) can be separated into three groups which we call as $m = 0$, $|m| = 1$, and $|m| = 2$. We do this separation as follows. At the $\bar{M}$ point (and at the $\bar{\Gamma}$ point), electron states are classified according to irreducible representations of the group C_{4v} . This group has four one-dimensional representations Δ_1 , $\Delta_{1'}$, Δ_2 , and $\Delta_{2'}$ and one two-dimensional representation Δ_5 . At nanowire atoms the $\{s-p_z-d_{3z^2-r^2}\}$, $\{p_x-d_{xz}, p_y-d_{yz}\}$, $\{d_{x^2-y^2}\}$, and $\{d_{xy}\}$ atomic orbitals transform according to Δ_1 , Δ_5 , Δ_2 , and $\Delta_{2'}$ representations, respectively. Therefore, we can assign $m = 0$ to states of Δ_1 , $|m| = 1$ to states of Δ_5 , and $|m| = 2$ to states of Δ_2 and $\Delta_{2'}$. Note that there will be in principle smaller contributions from higher atomic states such as f , g , but that is not very important. Similarly, in a transmission calculation each transmission eigenchannel (obtained by diagonalizing the Hermitian matrix $\mathbf{T}^\dagger \mathbf{T}$, $\mathbf{T}$ being the transmission matrix[35]) is clearly associated with a well defined $|m|$ so that the total transmission is naturally decomposed onto contributions from $m = 0$, $|m| = 1$, and $|m| = 2$.

Let us consider majority spin first (Fig. 4). All the $\bar{M}$ point electron states as a function of k_z are plotted by thin lines. Moreover, the states of $m = 0$ symmetry are marked by circles when their squared wave-functions have a charge on the nanowire larger than 4%. The amount of charge for these states on both the first contact atom and the nanowire middle atom (central atom) is given by the height of vertical lines on the LDOS panels. In Ni all spin up d states are occupied so that the corresponding bands of $|m| = 1$ and $|m| = 2$ symmetry lie well below the Fermi energy. They are clearly visible in Fig 4 as the crowd of localized states amassed below energy -0.5 eV. These states should not participate to electron transport and we do not display in Fig. 4 the data for $|m| = 1$ and $|m| = 2$. Around the Fermi energy the extended $m = 0$ states through the wire have

FIG. 4: Supercell band structure for the majority spin of the relaxed three-atom Ni wire calculated along the z direction at the $\bar{M}$ point of the 2D BZ. Each electron state can be labeled by a certain $|m|$, where m is the projection of the angular momentum on the nanowire axis (see text). The circles mark the states of $m = 0$ symmetry having the charge on the wire larger than some threshold value (see text) while the states of $|m| = 1$ and $|m| = 2$ symmetry are not presented since they are irrelevant for electron transport. For each $m = 0$ state, the charge on the contact and central atoms of the wire is given by vertical line s on the LDOS panel. The electron transmission of the $m = 0$ channel is also shown.

mainly $s - p_z$ character. They give rise to a dispersive band as shown in Fig. 4. Accordingly, the transmission of the $m = 0$ channel is a smooth function of energy and is close to 1, because the s band is broad, and with its high kinetic energy it is very poorly reflected at the nanocontact. Below -0.75 eV, however, the $s - p_z$ states hybridize strongly with $d_{3z^2-r^2}$ states, making their effective dispersion much flatter, or the effective mass along z much bigger. As a result, in this energy region well below E_F the $|m|=0$ transmission drops well below 1, developing a strong energy dependence.

The situation is considerably richer for minority spin (Fig. 5). Here the d states of the nanowire are partially occupied and contribute to transmission around the Fermi energy. Therefore, in Fig. 5 we also present the panels for $|m| = 1$ (b) and $|m| = 2$ (c). We mark the states by circles if their charge on the nanowire is larger than 4% (for $|m| = 1$) and 16% (for $|m| = 2$). For the $m = 0$ channel, the dispersive $s - p_z$ band ends well above E_F at an energy about 0.4 eV. The Fermi energy falls inside the energy region of strong $s - p_z - d_{3z^2-r^2}$ hybridization. Here, for all $|m|$, the electron bands are quite narrow which leads to significant energy variations of the corresponding transmission function. As anticipated there is a clear correlation between sharp features in the transmission as a function of energy and the presence of extended states. For example, the maximum in

FIG. 5: The same as in Fig. 4 but for the minority spin channel. In addition to $m = 0$ states (a), the corresponding data for the states of $|m| = 1$ (b) and of $|m| = 2$ (c) symmetry (which now contribute to the transmission around the Fermi energy) are also shown.

the transmission for the $m = 0$ channel just below the Fermi energy corresponds to a slightly dispersive band with mainly $d_{3z^2-r^2}$ character. Similarly, the maxima in the $|m| = 1$ transmission at about -1.1 , -0.5 , -0.1 , and 0.4 eV agree with the extended bands seen at those energies.

It should be emphasized, however, that there are some aspects in the transmission function which can not be

understood solely from the band structure analysis. For instance, the energy band of $m = 0$ symmetry has a small gap at an energy around -0.3 eV (majority spin) or 0.3 eV (minority spin) where the transmission function remains continuous and does not drop to zero. This is because the transmission function is really calculated for an infinite lead-nanocontact-lead open system (and should be in principle compared with the LDOS constructed via scattering states), whereas the LDOS shown refers to the nanocontact alone, closed onto itself via periodic boundary conditions in the z direction. The two will approach one another only when increasing conceptually the number of bulk planes included in the supercell to infinity. The energy bands will then continuously change so that the band gap discussed above (which is an artifact of the periodic boundary condition along the z axis) will eventually disappear. We actually tested these conclusions using a simple tight-binding model. Note that the only quantity obtained from supercell calculations and needed for evaluation of transmission function is the self-consistent potential which turns out to converge much better (than the LDOS) with the length of the supercell.

One feature which is important to underline again with regard to the $m = 0$ minority spin channel is that its transmission at E_F is well below 1, despite a massive presence of s states. This is clearly the result of a geometry-induced hybridization of $s - p_z$ states – by themselves highly conductive – with the poorly conductive $d_{3z^2-r^2}$ states. We expect this hybridization to be in fact more general than the assumed 3-atom nanowire geometry, and the s -channel transmission reduction to carry over to all cases where hybridization is allowed by symmetry. This observation will be useful later.

BALLISTIC CONDUCTANCE

We now present the ($\mathbf{k}_\perp$ -integrated) transmission function of the 3-atom suspended Ni nanowire in the relaxed configuration (Fig. 6). On the upper panel we show the total transmission for the majority (up) and minority (down) spin channels. To understand better the different features in the transmission curves we separate on the lower panels the total transmission onto contributions from different $|m|$ and also show the LDOS at the middle nanowire atom of the corresponding symmetry. At arbitrary $\mathbf{k}_\perp$ (unlike the $\bar{M}$ or the $\bar{\Gamma}$ point), the transmission eigenchannels are not associated to a certain $|m|$ but have, in general, contributions from all the $|m|$. Therefore we decompose the total transmission as follows. For each $\mathbf{k}_\perp$ and for each transmission eigenchannel j the charge inside a sphere of some radius r_0 (volume V_0) surrounding the middle nanowire atom is calculated as $n_j = \int_{V_0} |\psi_j(\mathbf{r})|^2 d\mathbf{r}$. It can be further decomposed onto contributions from different lm (in our calculations $l = 0, 1$, and 2): $n_j = \sum_{lm} n_{j,lm}$, where

FIG. 6: Spin-dependent transmission function of the Ni nanowire in the fully relaxed configuration (upper panel). The lower panels display the symmetry decomposition of the transmission function and of the LDOS at the mid-nanowire atom.

$n_{j,lm} = \int_0^{r_0} |R_{j,lm}(r)|^2 r^2 dr$ and the projections $R_{j,lm}(r)$ are obtained from $R_{j,lm}(r) = \int Y_{lm}^*(\Omega) \psi_j(r, \Omega) d\Omega$. The transmission of each eigenchannel is then weighted by its charge of a certain symmetry. For example, the contribution of the j -th channel to the transmission of $m = 0$ symmetry is given by $T_j(1/n_j) \sum_l n_{j,l0}$. The contributions from different $\mathbf{k}_\perp$ and from different eigenchannels are then properly added to produce the final value.

We first discuss the transmission function for the majority spin channel (spin up). Here, the transmission around the Fermi energy is almost 1 and it is due to nearly free propagation of the $s - p_z$ state ($m = 0$). Since the spin up d states of the wire are occupied, the $|m| = 1$ and the $|m| = 2$ channels contribute to the total transmission only at energies lower than E_F . Moreover, at E_F the $|m| = 1$ channel gives rise only to a small tunneling current while the $|m| = 2$ channel is completely closed. For the minority spin channel (spin down), the

transmission curves are qualitatively similar to majority spin channel but are shifted to higher energies due to the exchange gap, which in the Ni nanowire is ~ 1.25 eV. At the Fermi energy there are now down spin d states available for transport. The transmission of the $m = 0$ channel at the Fermi energy is still close to 1 but shows a strong energy dependence and corresponds to a mainly $d_{3z^2-r^2}$ LDOS peak at the central nanowire atom. The transmission function for the $|m| = 1$ channel shows two broad maxima around -1.1 eV and 0.4 eV. They are associated with two double degenerate $d_{xz,yz}$ states of the three atom Ni wire. A third state is located at lower energy (about -2.2 eV) and is not shown in Fig. 6. These three states will develop – upon increasing the nanowire length – into a twofold degenerate band with bandwidth about 3 eV. We find that the Fermi energy is located between two states of higher energy and the $|m| = 1$ channel contributes here about 0.7 to the total transmission. The remaining $|m| = 2$ channel corresponds to a very narrow twofold degenerate d_{xy,x^2-y^2} band of an infinite wire (the bandwidth is about 0.6 eV). This band, however, crosses the Fermi energy. Therefore, right below the Fermi energy one has a noticeable contribution from the $|m| = 2$ channel to the total transmission while its transmission at the E_F is about 0.5. This channel is responsible for a transmission peak at the energy -0.1 eV.

We can further investigate how the structural relaxation affects electron transport. In Fig. 7 we present the transmission function of the Ni nanowire in the unrelaxed initial configuration. Similarly to the relaxed configuration (Fig. 6), we also report the symmetry-decomposed transmission as well as the LDOS at the nanowire central atom. One can see that the main conclusions drawn for the relaxed configuration remain unchanged. The majority spin transmission at the Fermi energy is about 0.8 and is again dominated by the s -like channel. Separating the minority spin transmission at the Fermi energy, one obtains values of 1.0, 0.7, and 0.2 from $m = 0$, $|m| = 1$, and $|m| = 2$ channels, respectively. Due to larger wire-lead separation in the unrelaxed configuration (parameter D in Table. 1), the nanowire states are less coupled to the leads. As a result, the peaks in transmission curves get sharper (see, e.g., two peaks for the $|m| = 1$ channel and the peak for the $|m| = 2$ channel). This leads to the smaller transmission at the Fermi energy for the $|m| = 2$ channel – 0.2 versus 0.5 in the relaxed configuration (see Fig. 6). For the $|m| = 1$ channel, the longer interatomic bonds in the wire (parameter d in Table. 1) lead to the fact that the two maxima in the transmission are less separated in energy and move closer to the Fermi level. This compensates the previous effect so that the transmission at the Fermi energy for the $|m| = 1$ channel does not practically change compared to the relaxed configuration.

We can now translate all results into a calculated ballistic conductance. From the total transmission at

FIG. 7: The same as in Fig. 6 but for the Ni nanowire in unrelaxed configuration.

the Fermi energy we obtain a conductance $G \approx (0.5 + 1.1) G_0 = 1.6 G_0$ and $G \approx (0.4 + 0.95) G_0 = 1.35 G_0$ for relaxed and unrelaxed nanowires, respectively. The conductance for the relaxed configuration turns out to be larger with respect to the unrelaxed case which is reasonable because of smaller lead-nanowire separation (better contact). The calculated conductances are in good agreement with break-junction measurements showing a quite broad first conductance peak centered at $1.6 G_0$ [7] or at $1.3 G_0$. [6] The breadth of the measured conductance histogram peak can be explained by observing that the detailed nanocontact conductance depends noticeably on the detailed geometry of the lead-nanocontact structure, as was seen for example by comparison of the relaxed and unrelaxed three-atom geometries. Recently, Bagrets *et al.*[21] calculated the ballistic conductance of a three-atom Co nanowire suspended between two Co(001) leads. They considered an unrelaxed nanowire (which corresponds to our unrelaxed configuration) and reported val-

ues close to $0.5 G_0$ for both majority and minority spin conductances. In comparison with our Ni results that finding is somewhat puzzling, as we obtain a much higher minority spin conductance due to a sizable contribution from the d electrons. In this respect, our results are closer to recent conductance calculations performed by Jacob *et al.*[22] They studied nanocontacts formed by two Ni atoms joining the two Ni electrodes and also found a non zero conductance from minority spin d states at low nanocontact stretching.

We should also stress that conductances reported here are much smaller than the ideal one for an infinite tipless monatomic wire $G = 3.5 G_0$, where in the absence of any reflection the conductance is just equal to the number of bands at the Fermi energy which is 7. The reduction from this ideal 3.5 conductance to the real 1.6 is due to the fact that d electrons are reflected by about 75%, and also to $s - d$ hybridization. On the other hand, this limited transmission effect is not as drastic as the predicted effect of a magnetization reversal (or “domain wall”) built into an infinite nanowire.[19] In the latter case all the d channels are completely blocked at the Fermi energy so that conductance of the nanowire was only $G = 1 G_0$ due to two (one per spin) s -like channels.

CONCLUSIONS

To summarize, we have presented DFT calculations of the structural and magnetic properties of the three-atom Ni nanowire suspended between two semi-infinite Ni(001) leads. A scattering-based approach was applied to study ballistic transport in both unrelaxed and relaxed configurations of the nanowire. Our calculations show that in both atomic configurations the majority spin conductance is attributed to one s -like channel and is, therefore, very close to $0.5 G_0$. On the contrary, the minority spin conductance has also noticeable contribution from the d states and is higher – $1.35 G_0$ and $1.6 G_0$ for unrelaxed and relaxed configurations, respectively. We found that overall conductances are quite close to recent experimental break junction results. Moreover, the fact that conductance is sensitive to the details of underlying atomic structure could account for a quite broad first peak in conductance histograms observed in experiment.

 - [29] The amount of contraction depends on the specific second layer atom since not all atoms here are equivalent (unlike the surface plane atoms). For example, the second layer atom beneath the nanowire end atom moves noticeably outwards by about 0.05 Å, or 2.8% d_{12}^0 relative to the surface plane. Two other (mutually equivalent) atoms of the second layer located on the sides of the square xy supercell move outwards by only about 1.6% d_{12}^0 while the fourth second layer atom (located on the diagonal of the square xy supercell) relaxes by only 0.8% d_{12}^0 .

 - [31] Additional atoms of the second layer lacking equivalent atoms in the (2×2) geometry were added at the same z value as that of the fourth second layer atom described in Ref. 29. Four new atoms were also added to form the $(2\sqrt{2} \times 2\sqrt{2})$ outermost surface layer in such a way that their distance to the added second layer atoms was equal to the first interlayer distance calculated for a relaxed Ni(001) surface, namely 1.7 Å. The atomic configuration so obtained was finally checked for residual atomic forces less than 5 mRy/a.u.

 - [33] In the specific example of a short Al nanowire suspended between two Al(001) leads, we considered (2×2) , $(2\sqrt{2} \times 2\sqrt{2})$, and (4×4) supercell geometries, and found that a reasonably converged transmission function is obtained already with the $(2\sqrt{2} \times 2\sqrt{2})$ xy size, a $\mathbf{k}_\perp$ integration being performed using 10 special $\mathbf{k}_\perp$ points. This xy geometry and BZ sampling were then adopted also for Ni nanowires.
